Logistic Regression

Regression vs Classification

regression

curve fit: finding model parameters by **minimizing** χ^2

$$\chi^2 = \sum_k \frac{(\hat{y}_k - y_k)^2}{\sigma_k^2}$$

turning an image the right way:

- **maximizing** autocorrelation function
- training an AI

Regression vs Classification

regression

classification

cat

dog

note: we can use (non-linear) regression for classification!

idea: data point y_k in N dimensional space

$$\rightarrow y_k = f(x_1, \dots, x_n, \dots, x_N) + \epsilon_k \quad \text{for each data point } k$$

ansatz:

$$y_k = \beta_0 + \sum_{n=1}^N \beta_n x_{kn} + \epsilon_k \quad \text{linear combination}$$

y : response
 x : regressors (assumed to be independent)
 β : factors (how a regressor contributes to the response)
 β_0 : intercept
 ϵ : error (stochasticity of the data, assumed to be normally dist.)

β_n : how strong does x_n affect y_k

y : response
 x : regressors (assumed to be independent)
 β : factors
 β_0 : intercept
 ϵ : error (stochasticity of the data, assumed to be normally dist.)

$$y_k = \beta_0 + \sum_{n=1}^N \beta_n x_{kn} + \epsilon_k$$

	x_1	x_2	x_3	x_4	x_5	y_k
	molecular_weight	electronegativity	bond_lengths	num_hydrogen_bonds	logP	toxicity_score
0	341.704142	2.655846	3.094069	2	9.111473	80.928052
1	335.950798	3.222621	2.890393	7	8.928483	83.491053

- Some Statistics
- a Python example

Logistic Regression

linear $\neq$ not curved

$$y_k = \beta_0 + \sum_{n=1}^N \beta_n x_n^n + \epsilon_k \quad \dots \text{is still linear}$$

just define: $\bar{x}_n := x_n^n$

$$y_k = \beta_1 x_n^{\beta_2} \quad \dots \text{is still linear}$$

just use log: $\bar{y}_k = \log(y_k) = \log(\beta_1) + \beta_2 \log(x_n) = \bar{\beta}_1 + \beta_2 \bar{x}_n$

As long as we can recover the linear structure by any transformation $\rightarrow$ it is linear

in part. log scaling is quite common examples:

- log fold change (DESeq/RNASeq)
- log odds ratio (comparing models, HMM)
- sound $\rightarrow$ dB is a log unit
- log incidence rates (medical studies)
- percentiles (medical studies)
-

y:	response
x:	regressors
β :	factors
β_0 :	intercept
ϵ :	error

...what is **not** linear?

$$y_k = \beta_0 + \beta_1 x_n \quad \beta_2 \quad \text{log trick does not work here}$$

general: linear refers to the **factors**

$$y_k = \beta_0 + \beta_1 x_1 + \beta_2 x_2 \quad \text{2D plane in 3D space}$$

$$y_k = \beta_0 + \beta_1 x_1^2 + \beta_2 x_2^2 \quad \text{2D parabolic}$$

$$y_k = \beta_0 + \beta_1 x_1^2 - \beta_2 x_2^2 \quad \text{2D hyperbolic}$$

...and many more...

y :	response
x :	regressors
β :	factors
β_0 :	intercept
ϵ :	error

all linear

$$y_k = \beta_0 + \sum_{n=1}^N \beta_n x_{kn} + \epsilon_k$$

...what is **not** linear?

$$y_k = \beta_0 + \beta_1 x_n^{\beta_2} \quad \text{log trick does not work here}$$

y:	response
x:	regressors
β :	factors
β_0 :	intercept
ϵ :	error

surfaces that **can't** be modelled by a linear transformation:

$$y_k = \beta_0 + \sum_{n=1}^N \beta_n x_{kn} + \epsilon_k$$

cross surface

Klein bottle

- a Python example

Logistic Regression

for K data points in N dimensional space

$$y_k = \beta_0 + \sum_{n=1}^N \beta_n x_{kn} + \epsilon_k$$

y :	response
x :	regressors
β :	factors
β_0 :	intercept
ϵ :	error

$$\underbrace{\begin{pmatrix} y_1 \\ \vdots \\ y_k \\ \vdots \\ y_K \end{pmatrix}}_Y = \underbrace{\begin{pmatrix} 1 & x_{11} & x_{12} & \dots & x_{1n} & \dots & x_{1N} \\ \vdots & \vdots & \vdots & & \vdots & & \vdots \\ 1 & x_{k1} & & & x_{kn} & & \\ \vdots & \vdots & & & \vdots & & \vdots \\ 1 & \vdots & & & \vdots & & \vdots \\ 1 & x_{K1} & x_{K2} & \dots & x_{Kn} & \dots & x_{KN} \end{pmatrix}}_X \underbrace{\begin{pmatrix} \beta_0 \\ \beta_1 \\ \vdots \\ \beta_n \\ \vdots \\ \beta_N \end{pmatrix}}_{\beta} + \underbrace{\begin{pmatrix} \epsilon_1 \\ \epsilon_2 \\ \vdots \\ \epsilon_k \\ \vdots \\ \epsilon_K \end{pmatrix}}_{\epsilon}$$

$$Y = X\beta + \epsilon$$

fitting: finding the best β in terms of minimizing the errors

$$\hat{\beta} = \underset{\beta}{\operatorname{argmin}} \left\{ \frac{1}{K} \|Y - X\beta\|^2 \right\} \quad (Y - X\beta)^T (Y - X\beta) = \sum_k \epsilon_k^2$$

$$Y = X\beta + \varepsilon$$

fitting: finding the best β in by minimizing the errors

$$(Y - X\beta)^T(Y - X\beta) = \sum_k \varepsilon_k^2$$

$$\frac{\partial}{\partial \beta} \sum_k \varepsilon_k^2 = 0 \longrightarrow \beta_{best} = \hat{\beta} = (X^T X)^{-1} X^T Y \longrightarrow \hat{Y} = X\hat{\beta} = \underbrace{X(X^T X)^{-1} X^T}_{\text{hat matrix } H} Y$$

some properties of the hat matrix:

- $H = H^T$ (symmetry)
- $HH = H \rightarrow H^n = H$ (idempotency)

$$\hat{Y} = X\hat{\beta} = X(X^T X)^{-1} X^T Y$$

all observables!

evaluating the fit:

$$\hat{\varepsilon} = Y - X\hat{\beta} = Y - \hat{Y} = (I - H)Y$$

$$\hat{\varepsilon}^T \hat{\varepsilon} = [(I - H)Y]^T (I - H)Y = Y^T (I - H)^T (I - H)Y = Y^T (I - H)Y$$

sum of squared errors (SSE)

y:	response
x:	regressors
β :	factors
β_0 :	intercept
ε :	error

summary:

the model:

$$Y = X\beta + \varepsilon$$

the fit:

$$\hat{Y} = X\hat{\beta} = X(X^T X)^{-1} X^T Y$$

sum of squared errors (SSE):

$$\hat{\varepsilon}^T \hat{\varepsilon} = Y^T (I - H) Y$$

(after the fit)

mean of squared errors (MSE):

$$\frac{\hat{\varepsilon}^T \hat{\varepsilon}}{K - N}$$

(after the fit)

often fit quality is judged by

$$R^2 := 1 - \frac{\sum_k (\hat{y}_k - y_k)^2}{\sum_k (y_k - \langle y \rangle)^2}$$

or adjusted R^2

$$\bar{R}^2 := R^2 - (1 - R^2) \frac{K}{N - K - 1}$$

and it is said that the fit is good if R^2 is close to one....

...but that is not true...

y:	response
x:	regressors
β:	factors
β_0:	intercept
ε:	error
K:	number of data points
N:	number of model param

$$\chi_{red}^2 = \frac{1}{df} \sum_{k=1}^K \left(\frac{y_k - \hat{y}_k}{\sigma_k} \right)^2 \quad df = K - N - 1$$

y_k :	measured value of data point
σ_k :	statistical error of y_i (often aka ey_i)
$\hat{y}_k$:	prediction by the model <i>after the fit</i>
K :	number of data points
N :	number of fit parameter

def:

$\bar{y}$: mean of the data point values

$$R^2 = 1 - \frac{\sum_{i=1}^K (y_k - \hat{y}_k)^2}{\sum_{i=1}^K (y_k - \bar{y})^2}$$

variance data vs model
(aka residual sum of squares)

variance of the data
(aka total sum of squares)

Note: do not confuse R^2 with Pearsons coefficient: $\rho = \frac{cov(x,y)}{\sqrt{var(x)var(y)}}$

$$\chi^2_{red} = \frac{1}{df} \sum_{k=1}^K \left(\frac{y_k - \hat{y}_k}{\sigma_k} \right)^2$$

$$df = K - N - 1$$

- scales difference between model and data to the error bars
- can be directly translated to a p-value via the Students distribution

H0: the fitted model has in fact generated the data

$$R^2 = 1 - \frac{\sum_{k=1}^K (y_k - \hat{y}_k)^2}{\sum_{k=1}^K (y_k - \bar{y})^2} \frac{\text{variance data vs model (aka residual sum of squares)}}{\text{variance of the data (aka total sum of squares)}}$$

$\bar{y}$: mean of the data point values

data variance can be huge
(i. e. exponential functions)
→ R^2 could be around 1.0
even if fit is completely off!

$$\chi_{red}^2 = \frac{1}{df} \sum_{k=1}^K \left(\frac{y_k - \hat{y}_k}{\sigma_k} \right)^2$$

$$df = K - N - 1$$

- scales difference between model and data to the error bars
- can be directly translated to a p-value via the Students distribution

H0: the fitted model has in fact generated the data

$$R^2 = 1 - \frac{\sum_{k=1}^K (y_k - \hat{y}_k)^2}{\sum_{k=1}^K (y_k - \bar{y})^2} \frac{\text{variance data vs model (aka residual sum of squares)}}{\text{variance of the data (aka total sum of squares)}}$$

$\bar{y}$: mean of the data point values

variance data vs model
(aka residual sum of squares)

variance of the data
(aka total sum of squares)

$$\approx 1 \rightarrow R^2 = 0$$

→ although the fit is good

$$\chi^2_{red} = \frac{1}{df} \sum_{k=1}^K \left(\frac{y_k - \hat{y}_k}{\sigma_k} \right)^2$$

$$df = K - N - 1$$

- scales difference between model and data to the error bars
- can be directly translated to a p-value via the Students distribution

H0: the fitted model has in fact generated the data

$$R^2 = 1 - \frac{\sum_{k=1}^K (y_k - \hat{y}_k)^2}{\sum_{k=1}^K (y_k - \bar{y})^2} \frac{\text{variance data vs model (aka residual sum of squares)}}{\text{variance of the data (aka total sum of squares)}}$$

$\bar{y}$: mean of the data point values

all plots: same R^2

$$\chi^2_{red} = \frac{1}{df} \sum_{k=1}^K \left(\frac{y_k - \hat{y}_k}{\sigma_k} \right)^2$$

$$df = K - N - 1$$

- scales difference between model and data to the error bars
- can be directly translated to a p-value via the Students distribution

H0: the fitted model has in fact generated the data

$$R^2 = 1 - \frac{\sum_{k=1}^K (y_k - \hat{y}_k)^2}{\sum_{k=1}^K (y_k - \bar{y})^2} \frac{\text{variance data vs model (aka residual sum of squares)}}{\text{variance of the data (aka total sum of squares)}}$$

$\bar{y}$: mean of the data point values

conclusion:

- R^2 is not a measure of the fit quality (but χ^2 is)
- error bars are important
- **given a good fit**, R^2 tells how strong the dependent variable responds to the independent variable

Also, Wiki is full of examples...

...and warnings (see “caveats” therein)

regularization:

λ Lagrangian Multiplier

$$\hat{\beta} = \underset{\beta}{\operatorname{argmin}} \left\{ \frac{1}{K} \|Y - X\beta\|^2 \right\}$$

$$\hat{\beta} = \underset{\beta}{\operatorname{argmin}} \left\{ \frac{1}{K} \|Y - X\beta\|^2 + \lambda \|\beta\|^1 \right\}$$

the Loss Function
 $L(X, Y, \lambda)$

L1 or **L**east **a**bsolute **s**hrinkage and **s**election **o**perator
- encourages **sparsity** of β
- reduces **overfitting**

$$\hat{\beta} = \underset{\beta}{\operatorname{argmin}} \left\{ \frac{1}{K} \|Y - X\beta\|^2 + \lambda \|\beta\|^2 \right\}$$

L2 or **R**idge
- **penalizes large β**

more detailed
explanation:

- discussion
- module 6

$$\hat{\beta} = \underset{\beta}{\operatorname{argmin}} \left\{ \frac{1}{K} \|Y - X\beta\|^2 + \lambda \max(0, -\beta) \right\} \quad - \text{penalizes negative } \beta$$

...and so on

log odds ratio: linear model

$\rightarrow$ probability for being in a certain state

$$p = \frac{e^{\beta_0 + \beta_1 x_1 + \dots}}{1 + e^{\beta_0 + \beta_1 x_1 + \dots}}$$

often:

$$\text{logit}(p) = \log\left(\frac{p}{1-p}\right)$$

examples:

- probability that a gene has been mutated
- probability of being diseased (cancer, alzheimer etc) as function of age, environmental influence etc ...
- Verhulst equation: $N(t) = N_0 \frac{e^{rt}}{C + e^{rt}}$
- activation functions in ANNs

$$\log\left(\frac{p}{1-p}\right) = \beta_0 + \sum_{n=1}^N \beta_n x_n + \epsilon$$

Note: one can derive the logit function from max. entropy too!

y:	response
x:	regressors (assumed to be independent)
β :	factors
β_0 :	intercept
ϵ :	error (stochasticity of the data, assumed to be normally dist.)

$$p = \frac{e^{\beta_0 + \beta_1 x_1 + \dots}}{1 + e^{\beta_0 + \beta_1 x_1 + \dots}} = \frac{1}{1 + e^{-\beta_0 - \beta_1 x_1 - \dots}}$$

onset of Alzheimer's disease (AD) is a function of **age** and years spent in **education**
(and other risk factors we ignore here for the sake of simplicity)

education: $d = x_1$ [yrs]

age: $a = x_2$ [yrs]

model:
$$p_{AD} = \frac{1}{1 + e^{-\beta_0 - \beta_1 d - \beta_2 a}}$$

+ data set + fit $\rightarrow$

$$\begin{aligned}\beta_0 &= +0.1 \\ \beta_1 &= -1.5 \\ \beta_2 &= +0.12\end{aligned}$$

- positive value $\rightarrow$ increasing p
- negative value $\rightarrow$ decreasing p
- intercept: "background" prevalence, not related to environmental/internal conditions

model:
$$p_{AD} = \frac{1}{1 + e^{-\beta_0 - \beta_1 d - \beta_2 a}}$$

education: $d = x_1$ [yrs] $\beta_0 = +0.1$
 age: $a = x_2$ [yrs] $\beta_1 = -1.5$
 $\beta_2 = +0.12$

y:	response
x:	regressors (assumed to be independent)
β :	factors
β_0 :	intercept
ε :	error (stochasticity of the data, assumed to be normally dist.)

example: **65yrs** old person, **8yrs** spent in education
 $\rightarrow p_{AD} = 1.6\%$

65yrs old person, **13yrs** spent in education
 $\rightarrow p_{AD} = 0.001\%$

How does education compensate aging?

$$p_{AD}(d + \bar{d}, a + \bar{a}) = p_{AD}(d, a)$$

$$\rightarrow \bar{a} = 12.5 \bar{d}$$

hence, one more year prolonged education compensates
12.5 years of aging
 (warning: don't confuse correlation with causation here!)

model:
$$p_{AD} = \frac{1}{1 + e^{-\beta_0 - \beta_1 d - \beta_2 a}}$$

education: $d = x_1$ [yrs] $\beta_0 = +0.1$
 age: $a = x_2$ [yrs] $\beta_1 = -1.5$
 $\beta_2 = +0.12$

y:	response
x:	regressors (assumed to be independent)
β :	factors
β_0 :	intercept
ε :	error (stochasticity of the data, assumed to be normally dist.)

How does the risk of onset changes *per year*?

relative change:

$$\frac{p_{AD}(a+1) - p_{AD}(a)}{p_{AD}(a)} \approx e^{\beta_2} - 1 \approx 12.7\%$$

$p_{AD} \ll 1$ (hence, for small Δa and “young” ages, i. e. below ≈ 80 yrs)

the risk of getting AD increases by 12.7% every year
 (warning: does not mean that it increases by 127% in ten yrs – we made an approximation!)

model:
$$p_{AD} = \frac{1}{1 + e^{-\beta_0 - \beta_1 d - \beta_2 a}}$$

education: $d = x_1$ [yrs] $\beta_0 = +0.1$
 age: $a = x_2$ [yrs] $\beta_1 = -1.5$
 $\beta_2 = +0.12$

y:	response
x:	regressors (assumed to be independent)
β :	factors
β_0 :	intercept
ε :	error (stochasticity of the data, assumed to be normally dist.)

How does the risk of onset changes *per year*?

more precise: relative change of the odds ratio

$$\frac{\frac{\partial}{\partial x_i} \left(\frac{p_{AD}}{1 - p_{AD}} \right)}{\frac{p_{AD}}{1 - p_{AD}}} = \beta_i$$

x_i is the desired regressor,
for example, age again (x_2)

the factors β_i indicate how strong (and in which direction) p changes
wrt a regressor x_i

let us return to the molecule data set:

```
Train = pd.read_csv("molecular_train_gbc_cat.csv")  
Test  = pd.read_csv("molecular_test_gbc_cat.csv")
```

- 1) loading data
- 2) plotting data
- 3) scaling data
- 4) fitting model
- 5) evaluating model

	molecular_weight	electronegativity	bond_lengths	num_hydrogen_bonds	logP	label
0	341.704142	2.655846	3.094069	2	9.111473	Toxic
1	335.950798	3.222621	2.890393	7	8.928483	Toxic
2	235.203185	2.441153	2.482026	1	6.497307	Non-Toxic
3	246.504930	2.766560	2.715472	7	7.450888	Non-Toxic
4	437.938926	3.480105	3.595688	3	10.915629	Non-Toxic

```
import statsmodels.api as sm
```

it is the same data set → plotting and scaling is as before

```
X = sm.add_constant(TrainS)
```

adding the
intercept

```
Y = pd.get_dummies(Train['Label'])
```

Python needs
True/False
as categorical

- 1) loading data
- 2) plotting data
- 3) scaling data
- 4) fitting model
- 5) evaluating model

```
In [48]: print(Y)
      Non-Toxic  Toxic
0         False   True
1         False   True
2          True  False
3          True  False
4          True  False
```

$$p = \frac{e^{\beta_0 + \beta_1 x_1 + \dots}}{1 + e^{\beta_0 + \beta_1 x_1 + \dots}}$$

we have two
states: toxic /
non-toxic

```
my_model = sm.GLM(Y, X, family = sm.families.Binomial()).fit()
```

```
my_model.summary()
```

GLM: general
linear model

it is the same data set → plotting and scaling is as before

```
X = sm.add_constant(TrainS)
Y = pd.get_dummies(Train['Label'])
```

```
my_model = sm.GLM(Y, X, family = sm.families.Binomial()).fit()
my_model.summary()
```

- 1) loading data
- 2) plotting data
- 3) scaling data
- 4) fitting model
- 5) evaluating model
